## Abstract

We investigated the effect of  $\text{ZrSi}_2$  and SiC doping on the microstructure, critical current density  $J_c$  and flux pinning of Fe-sheathed  $\text{MgB}_2$  tapes prepared by the *in situ* powder-in-tube method. Heat treatment was performed at a low temperature of 650 °C for 1 h. The phases, microstructures and flux pinning were characterized by means of x-ray diffraction, scanning electron microscope, magnetic and transport property measurements. It was found that the tapes doped with nanoscale SiC had the best pinning performance, while the  $\text{ZrSi}_2$  powder showed a similar improved field dependence of  $J_c$  compared with undoped samples.  $J_c$  values for the SiC doped samples were enhanced by two orders of magnitude at 4.2 K in magnetic fields above 8 T. At 4.2 K and 10 T, the  $J_c$  reached  $\sim 1.5 \times 10^4 \text{ A cm}^{-2}$ . Moreover, the critical temperature for the doped tapes decreased slightly ( $< 1.2 \text{ K}$ ). Microstructural analysis shows that very good grain connections or/and grain refinement were obtained for the doped tapes. The mechanism of the enhancement of the flux pinning is also discussed.

## 1. Introduction

The discovery of superconductivity at 39 K in the  $\text{MgB}_2$  compound has generated great interest in the field of applied superconductivity. Compared to conventional metallic superconductors (LTS),  $\text{MgB}_2$  has advantages of high transition temperature ( $T_c$ ) and low raw material costs of both B and Mg.  $\text{MgB}_2$  wires could become a credible competitor to LTS-based wires or to BSCCO-based wires used in low temperature ( $< 25 \text{ K}$ ) applications, such as a potential NMR or MRI magnet conductor. Indeed, superconducting  $\text{MgB}_2$  tape has been regarded as one of the most promising materials

for the next generation of superconductor applications [1]. The method commonly used to fabricate  $\text{MgB}_2$  tape is the powder-in-tube (PIT) technique [2, 3]. Many groups have made prototype tapes, using both prereacted (*ex situ*)  $\text{MgB}_2$  powder and mixtures of Mg and B powders, which must be reacted to  $\text{MgB}_2$  *in situ* within the tape.

By using PIT process, research efforts have been directed towards either improving critical current density ( $J_c$ ) by improving grain connectivity, or improving in-field performance through introducing pinning centres [4–6]. Several groups have reported that the nanometre-scale SiC doped *in situ* processed tapes show much higher  $J_c$  values

**Figure 1.** XRD patterns of undoped,  $\text{ZrSi}_2$  and nano-SiC doped tapes. The data were obtained after peeling off the Fe sheath. The XRD peaks of  $\text{MgB}_2$  are indexed, and the peaks of  $\text{MgO}$ ,  $\text{Zr}_3\text{Si}_2$ ,  $\text{Mg}_2\text{Si}$  and impurity are marked by asterisks, solid circles, open circles and forks, respectively. The peaks of Fe were contributed from the Fe sheath.

than undoped tapes [7, 8]. The suggested possible mechanism is that nano-SiC particles can result in the substitution of C in the B site and the formation of  $\text{Mg}_2\text{Si}$  nanometre inclusions, which greatly enhance the  $J_c$  property of  $\text{MgB}_2$  in high magnetic fields [7]. Besides SiC doping, Si particles [9] and several silicon compounds, such as  $\text{ZrSi}_2$ ,  $\text{WSi}_2$  [10] and  $\text{SiO}_2$  [8], have also been added into  $\text{MgB}_2$ , and all of them showed a positive effect in enhancing the  $J_c$  property of  $\text{MgB}_2$  superconductors. In this work, we have fabricated nanometre-scale SiC and micrometre  $\text{ZrSi}_2$  doped  $\text{MgB}_2$  tapes by using the PIT technique and investigated their doping effects on the microstructure and  $J_c$ - $B$  of  $\text{MgB}_2$  tapes.

## 2. Experimental details

Powders of magnesium (99.8% pure), amorphous boron (99.99%) and 5 at.% nanoscale SiC (20–50 nm) or  $\text{ZrSi}_2$  powders (–325 mesh) powders were used for the fabrication of tapes by the *in situ* powder-in-tube method. The sheath materials chosen for this experiment were commercially available pure Fe. Then the mixture was filled into an Fe tube of 8 mm outside diameter and 1.5 mm wall thickness. After packing, the tubes were swaged and drawn to a wire of

**Figure 2.** Typical EDX analysis of the SiC doped tapes. The peaks of Fe were contributed from the Fe sheath.

1.5 mm in diameter. The wires were subsequently rolled to tapes of  $\sim 3.2 \times 0.5$  mm. Finally, the tapes, wrapped in Ta foil, were sintered at temperatures of  $650^\circ\text{C}$  for 1 h in flowing high purity Ar. Undoped tapes were also similarly prepared for comparative study. The phase composition and microstructure were investigated using x-ray diffraction (XRD) and a scanning electron microscope (SEM). Magnetization measurements were performed with a superconducting quantum interference device magnetometer (SQUID). The transport  $J_c$  at 4.2 K and its magnetic field dependence were evaluated at the High Field Laboratory for Superconducting Materials (HFLSM), Sendai, by a standard four-probe technique with a criterion of  $1 \mu\text{V cm}^{-1}$ . The  $I_c$  measurement was performed for several samples to check reproducibility.

## 3. Results and discussion

Figure 1 shows the x-ray diffraction patterns of the superconducting cores of the undoped and doped tapes. As we can see, the undoped samples consist of a main phase,  $\text{MgB}_2$ , with minor impurity phases of  $\text{MgO}$  present. The same was found to be the case for both SiC and  $\text{ZrSi}_2$  doped tapes. In the case of SiC-added samples, we could not observe any peaks of SiC, which is similar to previous reports [7, 8]. The weak peak of  $\text{Mg}_2\text{Si}$  is observed in the XRD patterns of the SiC doped tapes if using a high speed scan, but the SEM/EDX analysis clearly shows that both Si and C are present within the  $\text{MgB}_2$  core of our doped tapes, as shown in figure 2. In addition, the position of both (100) and (110) peaks slightly shifts to higher angles due to SiC addition (see figure 3), meaning a decrease in the  $a$ -axis lattice parameter. However, the position of the (002) peak stays almost unchanged, indicating that nano-SiC doping has little effect on the  $c$ -axis. This is in good agreement with a recent report [11]. Further, the full width at half-maximum (FWHM) of the (110) peak for the SiC-added tapes is apparently larger than that of the corresponding peak for the undoped ones (figure 3). This broadening of the FWHM indicates inferior  $\text{MgB}_2$  crystallinity and lattice distortion of the core  $\text{MgB}_2$ , which usually resulted in an enhancement of the flux pinning strength [12]. On the other hand, XRD measurements revealed that the addition of  $\text{ZrSi}_2$  leads to the formation of  $\text{Zr}_3\text{Si}_2$  and  $\text{Mg}_2\text{Si}$  as the major impurity phases; there are no peaks corresponding to pure  $\text{ZrSi}_2$ , suggesting that

**Figure 3.** The enlarged view of XRD patterns near the (110) peak for undoped and nano-SiC doped tapes.

there were reactions between MgB<sub>2</sub> and ZrSi<sub>2</sub>, in agreement with the previous report [10].

It should be noted that our present undoped tapes have a rather high content of MgO, which may come from the Mg source and the fabrication process. This is also demonstrated by the lower  $T_c$  (see figure 6). Upon doping with either SiC or ZrSi<sub>2</sub>, both dopants would react with Mg, resulting in the formation of Mg<sub>2</sub>Si or others as the impurity phases. The formation of Mg<sub>2</sub>Si would decrease the content of MgO. This viewpoint is supported by the recent report that MgB<sub>2</sub> forms more easily at low temperature by the reaction of Mg with SiC powder [8].

Figure 4 shows the transport critical current density at 4.2 K in magnetic fields up to 14 T for the ZrSi<sub>2</sub> and SiC doped tapes. Only data above 4 T are shown, because in the lower field region,  $I_c$  was too high to be measured. From figure 4 we immediately notice that both doped samples exhibited a superior field performance and higher values of  $J_c$  than the undoped samples in magnetic fields of up to 14 T. In other words, the irreversibility field ( $H_{irr}$ ) of doped samples is significantly higher than for undoped ones. This suggests that both ZrSi<sub>2</sub> and SiC doping are enhancing  $H_{irr}$ . It is striking that, in contrast with the previous report [10], the magnetic field dependence of  $J_c$  for ZrSi<sub>2</sub> doped tapes does change with the ZrSi<sub>2</sub> addition in our study. At present, the reason is not completely understood. A possible explanation may be related to the different ZrSi<sub>2</sub> powders employed and different deformation processes in the two investigations. When we compare the ZrSi<sub>2</sub> and the SiC doped tapes, we should note the difference of the  $J_c$ - $B$  property. The  $J_c$  value of SiC doped tapes was higher than that of ZrSi<sub>2</sub> doped tape in

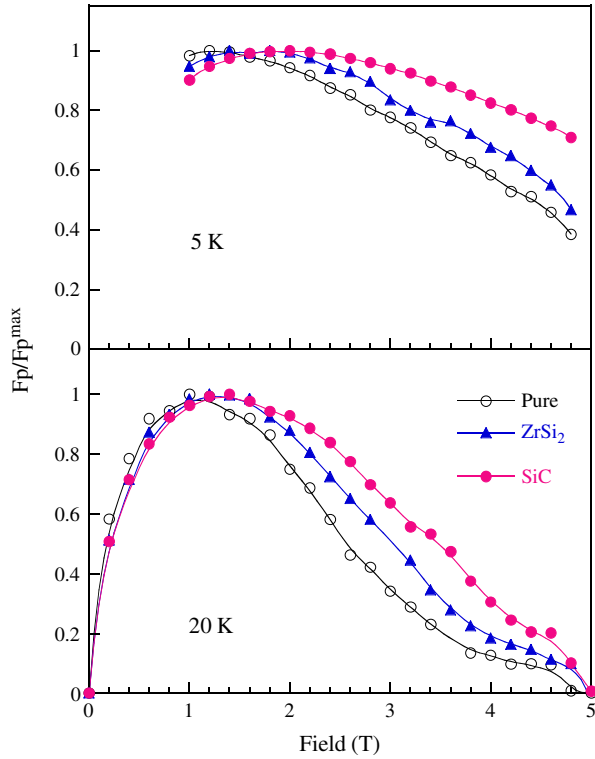

**Figure 4.** Transport  $J_c$  at  $T = 4.2$  K as a function of applied fields for undoped and doped samples. The measurements were performed in magnetic fields parallel to the tape surface.

the high magnetic fields, suggesting that nano-SiC doping is more effective in improving flux pinning than micrometre ZrSi<sub>2</sub> addition. Compared to the undoped tapes, the SiC doped tapes heated at 650 °C reveal the highest  $J_c$  values, increased by more than two orders of magnitude in higher magnetic fields. At 4.2 K, the transport  $I_c$  reached 164 A at 8 T ( $J_c = \sim 3.8 \times 10^4$  A cm<sup>-2</sup>) and 62 A at 10 T ( $J_c = \sim 1.5 \times 10^4$  A cm<sup>-2</sup>). These data for  $J_c$ - $B$  are quite comparable to the best results recently achieved for the nano-SiC doped MgB<sub>2</sub> tapes using MgH<sub>2</sub> + B powder [8]. It is noted that the  $J_c$  difference between tapes sintered at 650 and 700 °C are quite small as shown in figure 4, but the tape sintered at 700 °C seems to show a slightly weaker field dependence of  $J_c$ . This indicates that more nanoparticles acting as effective pinning centres are formed due to the higher sintering temperature.

To confirm the enhanced flux pinning ability in MgB<sub>2</sub> tapes with SiC and ZrSi<sub>2</sub> doping, figure 5 presents the normalized volume pinning force  $F_p(B)/F_p^{\max}$  as a function of magnetic field at 5 and 20 K for undoped and doped tapes heated at 650 °C. It is clear that the pinning force of both ZrSi<sub>2</sub> and SiC doped tapes is much larger than for the undoped ones over 1 T, indicating enhanced flux pinning in high fields. The samples with the SiC doping show the highest flux pinning force among the samples studied: the field where the maximum  $F_p(B)$  occurs is shifted to higher fields: e.g., at 20 K, the maximum  $F_p(B)$  difference is 0.4 T between the SiC doped and undoped samples, while at 5 K, the  $F_p^{\max}$  of SiC doped samples is up to 2 T—compared to the 1.2 T maximum of undoped ones. As we can see, ZrSi<sub>2</sub> particle also shows a pinning force enhancement, but it is not as strong as with nano-SiC. The maximum  $F_p(B)$  is only shifted to higher field by 0.2 T for the ZrSi<sub>2</sub> doped tapes in comparison to the undoped ones. Briefly, these results clearly demonstrated that the enhanced flux pinning as a result of SiC and ZrSi<sub>2</sub> doping should be responsible for the excellent transport  $J_c$ - $B$  properties of doped samples.

As shown in figure 6, the  $T_c$  onset for the undoped samples heated at 650 °C is  $\sim 35.2$  K. For the SiC doped samples,  $T_c$  only drops slightly, 1.2 K, indicating that SiC doping in MgB<sub>2</sub> tapes has little effect on  $T_c$ , which is quite important

**Figure 5.** Volume pinning force  $F_p$  versus  $B$  at various temperatures for undoped and doped tapes.

**Figure 6.** Normalized magnetic susceptibility versus temperature for all the doped and undoped tapes.

for practical applications. Note that the  $T_c$  decreases with increasing sintering temperature.  $T_c$  reaches 33.7 K for the tapes heat treated at 700 °C. Meanwhile, the onset  $T_c$  of the tapes with  $ZrSi_2$  addition reaches 34.2 K, and also decreases slightly, compared to the undoped ones. On the other hand, all doping slightly depressed  $T_c$  ( $< 1.2$  K), indicating that the dopant incorporates into the  $MgB_2$  structure. It is interesting to note that the  $ZrSi_2$  sample shows relatively large diamagnetic signal at temperatures of above  $T_c$ , which might be related to the ferromagnetic Fe particles coming from the iron sheath, as supported by the XRD data. Further study is now in progress.

**Figure 7.** Typical SEM images of the fractured  $MgB_2$  core layers of heat-treated Fe-sheathed tapes: (a) undoped, (b)  $ZrSi_2$  doped, (c) SiC doped.

In order to understand the mechanism for the enhancement of  $J_c$  at high fields, we studied the differences in microstructure of the tapes with and without doping. Figure 7 shows the typical SEM images of the fractured core layers for undoped and doped samples. SEM results clearly reveal that the  $MgB_2$  core of the undoped samples was loose with some limited melted intergrain regions. In contrast, much larger melted regions of intergrains were observed in the  $ZrSi_2$  doped tapes, resulting in the better connectivity between the  $MgB_2$  grains and increased  $J_c$  as mentioned before. On the other hand, the SiC doped samples had quite uniform microstructure with fewer voids, which also improved the linkages of grains. It is noted that we could not observe appreciate difference

**Figure 8.** TEM image of the SiC doped tape. MgB<sub>2</sub> grains with the size of <100 nm are clearly shown.

in grain size between the undoped and ZrSi<sub>2</sub>-added tapes. However, the grain size decreased drastically with the nano-SiC addition, with average values of ~200 and ~80 nm, for the undoped and doped tapes, respectively, as shown in figures 7 and 8. Obviously, the fine grain size would create many grain boundaries that may act as effective pinning centres, which might be one of reasons for the enhanced  $J_c$ - $B$  performance.

The significant enhancement of  $J_c$  and the improved irreversibility behaviour in the ZrSi<sub>2</sub> and SiC doped MgB<sub>2</sub> samples may be attributed to a good connection between grains and strong pinning in the samples. As revealed by microstructural analyses, the improvement in the grain connectivity as a consequence of densification of the tape core is effective for enhancing the  $J_c$ - $B$  properties. This was also corroborated by many recent results [5, 6]. However, this factor alone cannot fully explain the experimental results because the grain coupling mainly increases the  $J_c$  values, and hardly changes the magnetic field dependence of  $J_c$ , as reported previously [8, 10]. Therefore, the excellent  $J_c$  field performance is mainly due to nanoscale impurity precipitates or/and substituted crystal lattice defects introduced by SiC and ZrSi<sub>2</sub> doping. As supported by XRD and SEM/EDX results, ZrSi<sub>2</sub> addition resulted in Zr<sub>3</sub>Si<sub>2</sub> and Mg<sub>2</sub>Si as the major impurity phases, while high contents of Mg<sub>2</sub>Si, other impurity phases and large numbers of grain boundary structure were observed in the SiC doped samples sintered at low temperature. These reaction-induced products or the grain boundary structure can serve as strong pinning centres improving flux pinning, as evidenced by figure 5. As we have shown before, the enhanced pinning force with ZrSi<sub>2</sub> is not as strong as with nano-SiC; the reason is that the

grain size of the ZrSi<sub>2</sub> powder used was larger (~44 μm), so more large impurity phases introduced would not be effective pinning centres but act to reduce the superconducting volume. On the other hand, more nanoscale precipitates matching the coherence length well and grain boundary structures introduced by nano-SiC doping can act as strong pinning centres; thus the superior  $J_c$ - $B$  characteristic. Accordingly, the results of the present work indicate that a combination of improving grain coupling, reduced grain size and the strong flux pinning caused by nano-SiC doping is responsible for the significant enhancement of the  $J_c$ - $B$  performance in high magnetic fields. Note that further improvement in  $J_c$ - $B$  is expected on optimizing the processing parameters or utilization of nanometre ZrSi<sub>2</sub> particles.

#### 4. Conclusions

In summary, we have synthesized ZrSi<sub>2</sub> and SiC doped MgB<sub>2</sub>/Fe tapes by the *in situ* powder-in-tube method. The  $J_c$ - $B$  characteristics have been significantly improved in both doped tapes, in comparison with the undoped ones. These excellent values can be attributed to the very good grain connections as well as the strong flux pinning obtained in these doped tapes. This role of ZrSi<sub>2</sub> and SiC may be very beneficial in the fabrication of MgB<sub>2</sub> tapes for a large range of applications.

#### Acknowledgments

The authors would like to thank T Nishizaki, T Nojima and Y Hayasaka of Tohoku University for their kind help during the experiments. We also thank Hongli Suo for useful discussions.
